### **ABSTRACT**

Using the theoretical formalism of J. Hone (Dekker encyclopedia of Nano science and Nanotechnology, 2004), we have evaluated the temperature dependent thermal conductivity of isolated SWNT, 2D-graphene sheet, 3D-graphite and single MWNT. From these evaluations, it shows that the thermal properties of carbon nanotubes are dominated by phonons. The results also show that 1-D quantization of phonon band structure. Our theoretical results indicate that nanotube composite materials may be useful for thermal management applications.

**Keywords:** 1-D quantization of phonon band structure, 2D-graphene sheet, 3D-graphite, Umklapp process, nanowires, power law, relaxation time approximation, ballistic 1-D channel.

### **INTRODUCTION**

In an earlier paper<sup>1</sup>, we have presented a method of evaluation of specific heat (heat capacity) of carbon nanotubes. In this paper, we have presented a method of evaluation of temperature dependent thermal conductivity  $\kappa(T)$  of carbon nanotubes. Carbon-based materials (diamond and in-plane graphite) display the highest measured thermal conductivity of any

known materials at moderate temperatures<sup>2</sup>. In graphite, the thermal conductivity is generally dominated by phonons and limited by the small crystalline size within a sample. Thus the apparent long-range crystalline of nanotubes has led the speculation that the longitudinal thermal conductivity of nanotubes could possibly exceed the in-plane thermal conductivity of graphite. The thermal conductivity of graphite is generally dominated by phonons and because of long

phonon mean free-path in-plane thermal conductivity of graphite together with diamond has the highest thermal conductivity of known materials. The reason for very high thermal conductivity follows from the very high velocity of sound based on kinetic theory arguments and relates to very high Young's modulus of carbon nanotubes. Thermal conductivity increases as the tube diameter decreases. At low temperature thermal conductance of the carbon nanotubes bundles follows the power law  $T^\alpha$  where  $T$  is the temperature and  $\alpha$  is an exponent. The value of  $\alpha$  is less than 2 (around 1.5). This fact suggested that the thermal transport in the bundles is like that of a quasi-one-dimensional system. The same is true for specific heat. The measured specific heat differs from that of graphene and graphite, especially in the low temperature region, where the quantization of phonon band structure is observed. The more evident property of thermal conductivity in carbon nanotube is its increase as the carbon nanotube diameter decreases. A totally different behavior is observed in nanowires, where the thermal conductivity is reduced if the wire diameter is small. In nanowires, exponential  $\alpha$  in the power law  $T^\alpha$  ranges from 1 to 3 increasing from wire sections<sup>4</sup>.

Measurements of the temperature dependent thermal conductivity  $\kappa(T)$  for an individual MWNTs (14nm diameter)<sup>5</sup> show very high value of  $\kappa(T)$  more than  $3000 \text{ WmK}^{-1}$  comparable to graphite (in plane). Therefore, one needs a small diameter tubes, probably individual SWNTs to exhibit thermal conductivity greater than that of graphite.

## MATHEMATICAL FORMULAE USED IN THE EVALUATION

In general thermal conductivity  $\kappa$  is a tensor quantity but one considers only the diagonal elements

$$\kappa_{zz} = \sum C v_z^2 \tau \quad (1)$$

where  $C$  is the specific heat and  $v_z$  and  $\tau$  are group velocity and relaxation time of a given phonon state. At low temperature ( $T \ll \Theta_D$ ), the relaxation time is determined by scattering off fixed impurities, defects, sample boundaries etc. and is roughly constant. Therefore in ordinary materials, the low temperature thermal conductivity has the same temperature dependence as the specific heat. However, in anisotropic materials this relationship does not strictly hold. Because the concentration of each state is weighted by the scattering time and the square of velocity, the thermal conductivity preferentially sample state with high  $v$  and  $\tau$ . For example, in graphite, the thermal conductivity parallel to the basal planes is only weakly dependent on the interlayer phonons. In SWNTs bundles,  $\kappa(T)$  depends on the on-tube phonons rather than the inter tube mode.

The thermal conductivity due to phonon is limited to the perturbed phonon distribution  $b$  given as

$$b - b_0 = -\psi \frac{\partial b_0}{\partial (\hbar \omega)} \quad (2)$$

Where  $b_0$  is the equilibrium phonon distribution and  $\psi$  is a deviation function. The linearized Boltzmann equation for a

solid subjected to thermal gradient written in the relaxation time approximation, turns out to be<sup>6,7</sup>.

$$K_{\beta} T v \nabla T \frac{\partial b_0}{\partial T} = -\frac{1}{\tau} \psi b_0 (l + b_0) \quad (3)$$

Where  $v$  is the phonon group velocity and  $\tau$  is relaxation time. The heat current density  $U$  is defined for nanotube with volume  $\Omega = SL$ , where  $S$  is the section and  $L$  is the length. The expression of  $U$  is given by

$$U = -\frac{1}{2\pi S} \sum_{p,n} \int dq_z \hbar \omega v \psi \frac{\partial b_0}{\partial (\hbar \omega)} \quad (4)$$

where the sum on all the lattice wave numbers along the  $z$ -direction are evaluated with an integral. A thermal current exists along the tube  $z$ -axis, if the nanotube is subjected to a gradient  $\nabla T = \frac{\partial T}{\partial z}$ .  $v$  is the phonon velocity in the  $z$ -direction. The thermal conductivity is defined as the parameter  $\kappa$  joining the heat current with the thermal gradient

$$U = \kappa \frac{\partial T}{\partial z} \quad (5)$$

If the phonons are only subjected to boundary scattering, that is the scattering occurring at the end of the tube, the relaxation time is given by  $\tau = L/v$ . the thermal conductivity turns out to be

$$\kappa = \frac{\hbar^2 a^3 L}{2\pi K_{\beta} T^2 S} \left(\frac{\phi_0}{M}\right)^{\frac{3}{2}} \sum \int d\xi \bar{\omega}^{-2} v b_0 (l + b_0) \quad (6)$$

where

$$\omega = a \left(\frac{\phi_0}{M}\right)^{\frac{1}{2}} \bar{\omega}, \xi = cq_z, \bar{v} = \left| \frac{\partial \bar{\omega}}{\partial \xi} \right| \quad (7)$$

Equation (6) is the kinetic model of thermal conductivity, if  $\bar{v}$  is assumed equal to the mean value of the phonon velocity. For thermal conductivity of low -dimensional system i.e for 1-D ballistic electronic channel, the electronic conductance is quantized with a universal value of

$$G_0 = \frac{2e^2}{h} \quad (8(a))$$

Similarly for a single ballistic 1-D channel, the thermal conductance is independent of materials parameters and there exists a quantum of thermal conductance which is linear in  $T$

$$G_{eh} = \left(\frac{\pi^2 K_{\beta}^2}{3h}\right) T \quad (8(b))$$

Conditions for observations of this quantum were first examined in detail by Rego and Kirezenow<sup>9</sup>, using lithographically defined nano structure. Schwab *et al.*<sup>10</sup> confirmed this value experimentally.

At high temperatures three phonons Umklapp scattering begins to limit the phonon relaxation time. Therefore the phonon thermal conductivity displays a peak and decreases with increasing temperature. Umklapp scattering requires production of phonon beyond the Brillion zone boundary: because of the high Debye temperature of diamond and graphite. The peak in the thermal conductivity of these materials is

near 100K, significantly higher than most of the materials. In less crystalline forms of graphite, such as carbon fibers a peak in  $\kappa(T)$  occurs at higher temperatures because defect scattering remains dominant over umklapp scattering at higher temperatures<sup>11</sup>. In low dimensional systems, it is difficult to conserve both energy and momentum for umklapp process<sup>12</sup>, so it may be possible that umklapp scattering is suppressed in nanotube relative to 2D or 3D forms of carbon.

A measurement of  $\kappa(T)$  yields the combined contribution to the electrons and phonons. However, a simultaneous measurement of the electrical conductivity  $\sigma$  provides a measure of electron conductivity  $\kappa_e$  from the Wiedemann- Franz law<sup>11</sup>.

$$\frac{\kappa_e}{\sigma T} = L_o = 2.45 \times 10^{-8} \left( \frac{V}{K} \right)^2 \quad 8(c)$$

In this way, the phonon contributions can be deduced by subtracting the electronic contribution from the total measured thermal conductivity.

## DISCUSSION OF THE RESULTS

In this paper, we have theoretically evaluated the temperature dependent thermal conductivity  $\kappa(T)$  of isolated SWNT, 2D graphene sheet, 3D-graphite and single MWNT. The evaluation has been performed by the theoretical formalism of J. Hone<sup>13</sup>. In table T1, we have shown the evaluated results of temperature dependent thermal conductivity of SWNT for different diameters 10nm, 20nm and 50nm. The evaluated results were compared with the thermal conductivity of 14nm diameter. In

the experimental data<sup>14</sup>, they obtained the thermal conductivity of single carbon nanotubes, integer  $n$  and put equal to 150 the armchair tube diameter is 14nm. Now to have an agreement with experimental data, the nanotube length  $L$  must be equal to 6.2 $\mu$ m. From our results shown in table T1, The thermal conductivity  $\kappa(T)$  decreases with increasing diameter. In table T2, we have shown the evaluated results of temperature dependent thermal conductivity of an isolated SWNT. In this calculation,  $\kappa(T)$  has a peak near 100K and then decreases with increasing temperature. The value of  $\kappa$  at the peak ( $6.6 \times 10^4$  W/mK) and is near the highest thermal conductivity ever measured ( $4.1 \times 10^4$  W/mK) for an isotopically pure diamond sample at 104K. In table T3, we have shown the calculated thermal conductivity of nanotube as a function of temperature. Results were compared with the thermal conductivity of 2D- graphene sheet and 3D graphite<sup>15</sup>. In graphite, the interlayer interactions quench the thermal conductivity by nearly 1 order of magnitude. It is likely that the same process occurs in nanotubes bundles. Thus, it is significant that the coupling between tubes in bundles is weaker than expected. It may be that the weak coupling which is problematic for mechanical applications of nanotubes is an advantage for thermal applications. In table T4, we have shown the evaluated results of temperature dependent thermal conductivity of a bulk sample of SWNTs which has been aligned in a magnetic field. From our theoretical results it shows that  $\kappa(T)$  increases with the increasing temperature. It shows that in a magnetic field, the thermal conductivity is higher above 296W/mK at 300K, which is comparable to a good

metal<sup>16</sup>. In table T5, we have presented the evaluated results of thermal conductivity for SWNT samples with two diameter  $d=1.4\text{nm}$  and  $d=1.2\text{ nm}$ . Our theoretical results indicate that the smaller tube exhibit linear  $\kappa(T)$  up to higher temperature which is consistent with quantization effects<sup>17</sup>. In table T6, we have presented the evaluated results of thermal conductivity  $\kappa(T)$  of a single MWNT as a function of temperature.

Our theoretically evaluated results indicate that  $\kappa(T)$  increases as  $T^2$  up to 100K, attains a peak at 300K and then decreases with the increasing temperature. The quadratic temperature dependence is exactly what would be expected for large diameter nanotube which act as 2D graphene sheet. The room temperature value of  $\kappa(T)$  is over 2000W/mK. Some recent results<sup>18-25</sup> also reveals the same behavior.

## CONCLUSION

From the above theoretical calculations, it appears that the thermal properties of carbon nanotubes are dominated by phonons. These results show a direct evidence of 1-D quantization of the phonon bandwidth. It also suggests that the nanotube composite materials may be useful for thermal management applications.
